Orthogonal polynomials (in Matlab)

Walter Gautschi*

Department of Computer Sciences, Purdue University, West Lafayette, IN 47907-1389, USA

Received 26 September 2003; received in revised form 23 March 2004

Abstract

A suite of Matlab programs has been developed as part of the book “Orthogonal Polynomials: Computation and Approximation” Oxford University Press, Oxford, 2004, by Gautschi. The package contains routines for generating orthogonal polynomials as well as routines dealing with applications. In this paper, a brief review of the first part of the package is given, dealing with procedures for generating the three-term recurrence relation for orthogonal polynomials and more general recurrence relations for Sobolev orthogonal polynomials. Moment-based methods and discretization methods, and their implementation in Matlab, are among the principal topics discussed.

Keywords: Orthogonal polynomials; Recurrence relations; Matlab

1. Introduction

The analytic theory of orthogonal polynomials is well documented in a number of treatises; for classical orthogonal polynomials on the real line as well as on the circle, see [25], for those on the real line also see [24]. General orthogonal polynomials are dealt with in [5] and more recently in [22], especially with regard to n th-root asymptotics. The text [3] is rooted in continued fraction theory and recurrence relations.

While the theory of orthogonal polynomials is well developed, the practice of orthogonal polynomials—constructive, computational, and software aspects—is still in an early stage of development. An effort in this direction is being made by the author’s book [13] and the accompanying package *OPQ: a Matlab Suite of Programs for Generating Orthogonal Polynomials and Related Quadrature Rules*, which can be found at the URL <http://www.cs.purdue.edu/archives/2002/wxg/codes>.

E-mail address: wxg@cs.purdue.edu (W. Gautschi).

The purpose of the work in [13] is twofold: (i) to present various procedures for generating the coefficients of the recurrence relations satisfied by orthogonal polynomials on the real line and by Sobolev orthogonal polynomials; and (ii) to discuss selected applications of these recurrence relations, including numerical quadrature, least squares and moment-preserving spline approximation, and the summation of slowly convergent series. All is to be implemented in the form of Matlab scripts. In the present article we wish to give a brief account of the first part of [13]: the generation of recurrence coefficients for orthogonal polynomials and related Matlab programs. All Matlab routines mentioned in this paper, and many others, are downloadable individually from the above Web site.

2. Orthogonal polynomials

We begin with some basic facts about orthogonal polynomials on the real line and introduce appropriate notation as we go along. Suppose $d\lambda$ is a positive measure supported on an interval (or a set of disjoint intervals) on the real line such that all moments $\mu_r = \int_{\mathbb{R}} t^r d\lambda(t)$ exist and are finite. Then the inner product

$$(p, q)_{d\lambda} = \int_{\mathbb{R}} p(t)q(t) d\lambda(t) \quad (1)$$

is well defined for any polynomials p, q and gives rise to a unique system $\pi_r(t) = t^r + \dots$, $r = 0, 1, 2, \dots$, of monic orthogonal polynomials

$$\pi_k(\cdot) = \pi_k(\cdot; d\lambda) : \quad (\pi_k, \pi_\ell)_{d\lambda} \begin{cases} = 0, & k \neq \ell, \\ > 0, & k = \ell. \end{cases} \quad (2)$$

It is well known that they satisfy a three-term recurrence relation

$$\begin{aligned} \pi_{k+1}(t) &= (t - \alpha_k)\pi_k(t) - \beta_k\pi_{k-1}(t), \quad k = 0, 1, 2, \dots, \\ \pi_{-1}(t) &= 0, \quad \pi_0(t) = 1, \end{aligned} \quad (3)$$

where $\alpha_k = \alpha_k(d\lambda)$ and $\beta_k = \beta_k(d\lambda)$ are real resp. positive constants which depend on the measure $d\lambda$. For convenience, we define $\beta_0 = \int_{\mathbb{R}} d\lambda(t)$. Associated with the recurrence relation (3) is the *Jacobi matrix*

$$J(d\lambda) = \begin{bmatrix} \alpha_0 & \sqrt{\beta_1} & & & \mathbf{0} \\ \sqrt{\beta_1} & \alpha_1 & \sqrt{\beta_2} & & \\ & \sqrt{\beta_2} & \alpha_2 & \ddots & \\ & & \ddots & \ddots & \\ \mathbf{0} & & & & \end{bmatrix}, \quad (4)$$

a symmetric tridiagonal matrix of infinite order. Its leading principal minor matrix of order n will be denoted by

$$J_n(d\lambda) = J(d\lambda)_{[1:n, 1:n]}. \quad (5)$$

As already indicated in Section 1, the basic problem is this: for a given measure $d\lambda$ and for given integer $n \geq 1$, generate the first n coefficients $\alpha_k(d\lambda)$, $k = 0, 1, 2, \dots, n-1$, and the first n coefficients $\beta_k(d\lambda)$, $k = 0, 1, 2, \dots, n-1$, that is, the Jacobi matrix $J_n(d\lambda)$ of order n and β_0 .

α_{N-1}	β_{N-1}

Fig. 1. The array *ab* of recurrence coefficients.

2.1. Recurrence coefficients

Frequently, the measure $d\lambda$ is absolutely continuous, i.e., representable in the form

$$d\lambda(t) = w(t) dt, \quad (6)$$

where w is a nonnegative function, called *weight function*, integrable on the support of $d\lambda$ and not identically zero. Among the best-known weight functions are the classical weight functions, the more important of which are listed in Table 1.

For these, the recurrence coefficients are explicitly known. In Matlab, the first N recurrence coefficients are always stored in an $N \times 2$ array *ab* as shown in Fig. 1.

The Matlab command to compute them has the syntax $ab = r_name(parameters)$, where *name* identifies the weight function, and *parameters* is a list of parameters including N . Thus, for example, in the case of the Jacobi weight function, the Matlab command is

$$ab = r_jacobi(N, a, b).$$

Here, a, b are the Jacobi parameters (denoted by α and β in Table 1). If $\alpha = \beta$, it suffices to write $ab = r_jacobi(N, a)$, and if $\alpha = \beta = 0$, to write $ab = r_jacobi(N)$.

Demo#1: The first 10 recurrence coefficients for the Jacobi polynomials with parameters $\alpha = -\frac{1}{2}, \beta = \frac{3}{2}$.

The Matlab command, followed by the output, is shown in the box below.

```

Classical weight functions are not the only ones for which the recurrence coefficients are explicitly known. For example, the logistic weight function

$$w(t) = \frac{e^{-t}}{(1 + e^{-t})^2}, \quad t \in \mathbb{R},$$

of interest in statistics, has all coefficients $\alpha_k = 0$ (by symmetry) and $\beta_0 = 1$, $\beta_k = k^4 \pi^2 / (4k^2 - 1)$, $k \geq 1$ [3, Eq. (8.7) where $\lambda = 0$, $x = t/\pi$]. The corresponding Matlab routine is `r_logistic.m`. Other examples are measures occurring in the diatomic linear chain model, which are supported on two disjoint intervals, cf. [10].

Many nonclassical weight functions and measures, however, are such that their recurrence relations are not explicitly known. In these cases, numerical techniques must be used, some of which are to be described in the next four subsections.

2.2. Modified Chebyshev algorithm

In principle, the desired recurrence coefficients can be computed from well-known formulae expressing them in terms of Hankel-type determinants involving the moments μ_r of the given measure $d\lambda$. The problems with this are: excessive complexity and, more seriously, extreme numerical instability. To avoid these problems, one can attempt to use *modified moments*

$$m_r = \int_{\mathbb{R}} p_r(t) d\lambda(t), \quad r = 0, 1, 2, \dots, \quad (7)$$

where p_r are monic polynomials of degree r “close” in some sense to the desired polynomials π_r . In particular, they are assumed to also satisfy a three-term recurrence relation

$$\begin{aligned} p_{k+1}(t) &= (t - a_k)p_k(t) - b_k p_{k-1}(t), \quad k = 0, 1, 2, \dots, \\ p_{-1}(t) &= 0, \quad p_0(t) = 1, \end{aligned} \quad (8)$$

but this time with *known* coefficients $a_k \in \mathbb{R}$, $b_k \geq 0$. (We allow for zero coefficients b_k , since $a_k = b_k = 0$ yields the ordinary moments.) There is then a unique map

$$\mathbb{R}^{2n} \mapsto \mathbb{R}^{2n} : [m_k]_{k=0}^{2n-1} \mapsto [\alpha_k, \beta_k]_{k=0}^{n-1} \quad (9)$$

that takes the first $2n$ modified moments into the desired n recurrence coefficients α_k and β_k . An algorithm implementing this map has been developed by Sack and Donovan [21], and in more definitive form, by Wheeler [26]. In the case of ordinary moments ($a_k = b_k = 0$), it reduces to an algorithm already developed (for discrete measures) by Chebyshev [2]. We called it, therefore, the *modified Chebyshev algorithm*. It is implemented in the Matlab procedure

$$ab = \text{chebyshev}(N, \text{mom}, \text{abm}),$$

where N is the number n in (9), mom the $1 \times 2N$ array of modified moments, and abm the $(2N - 1) \times 2$ array of the first $2N - 1$ recurrence coefficients a_k, b_k in (8). If abm is omitted from the list of input parameters, the routine assumes $\text{abm} = \text{zeros}(2 * N - 1, 2)$, that is, ordinary moments.

In view of the highly ill-conditioned nature of map (9) when $m_r = \mu_r$ are ordinary moments, the conditioning of the modified moment map is an important question that has been studied already in [7], and more definitively in [9]. There are examples where the map is entirely well conditioned, but also others, especially when the measure $d\lambda$ has unbounded support, in which the map is almost as ill conditioned as for ordinary moments.

Demo#2: The weight function

$$w(t) = [(1 - \omega^2 t^2)(1 - t^2)]^{-1/2} \text{ on } [-1, 1], \quad 0 \leq \omega < 1,$$

of the “elliptic orthogonal polynomials”.

Since the weight function reduces to the Chebyshev weight function when $\omega = 0$, it seems natural to use as modified moments those relative to the monic Chebyshev polynomials,

$$m_0 = \int_{-1}^1 w(t) dt, \quad m_k = \frac{1}{2^{k-1}} \int_{-1}^1 T_k(t) w(t) dt, \quad k \geq 1.$$

Their computation, though not trivial by any means, can be accomplished in a very stable fashion [9, Example 3.3]. The first $2N$ of them are generated in the Matlab routine `mm_ell.m`. The following box shows the Matlab script required to generate elliptic polynomials.

```
function ab=r_elliptic(N,om2)
abm=r_jacobi(2*N-1,-1/2);
mom=mm_ell(N,om2);
ab=chebyshev(N,mom,abm);
```

The routine works well even for ω^2 quite close to 1, as is shown by the output below (displayed only partially) for $N = 40$, $\omega^2 = .999$.

```

ab =
    0  9.682265121100620e+00

    0  2.499932210069769e-01

```

All coefficients are accurate to machine precision.

2.3. Discrete Stieltjes and Lanczos algorithm

Partly in preparation for the next subsection, we now consider a *discrete N -point measure*

$$d\lambda_N(t) = \sum_{k=1}^N w_k \delta(t - x_k), \quad w_k > 0, \quad (10)$$

where δ is the Dirac delta function. Thus, the measure is supported on N distinct points x_k on the real axis, where it has positive jumps w_k . The corresponding inner product is a finite sum,

$$(p, q)_N = \int_{\mathbb{R}} p(t)q(t) d\lambda_N(t) = \sum_{k=1}^N w_k p(x_k)q(x_k). \quad (11)$$

There is now only a finite number, N , of recurrence coefficients $\alpha_k = \alpha_k(d\lambda_N)$, $\beta_k = \beta_k(d\lambda_N)$, which can be computed by either of two algorithms, one mentioned briefly by Stieltjes [23], and a more recent one based on ideas of Lanczos [18].

The former combines Darboux's formulae for the recurrence coefficients,

$$\begin{aligned} \alpha_k &= \frac{(t\pi_k, \pi_k)_N}{(\pi_k, \pi_k)_N}, \quad k = 0, 1, \dots, n-1, \\ \beta_k &= \frac{(\pi_k, \pi_k)_N}{(\pi_{k-1}, \pi_{k-1})_N}, \quad k = 1, 2, \dots, n-1, \end{aligned} \quad (12)$$

with the recurrence relation (3). In (12), the π_k are the (as yet unknown) discrete orthogonal polynomials $\pi_k(\cdot; d\lambda_N)$. *Stieltjes's Procedure* consists in starting with $k = 0$ and successively increasing k by 1 until $k = n - 1$. Thus, when $k = 0$, we have $\pi_0 = 1$, so that α_0 can be computed by the top relation in (12) with $k = 0$ and β_0 by $\beta_0 = \sum_{k=1}^N w_k$. With α_0, β_0 at hand, we can go into (3) with $k = 0$ and compute $\pi_1(x_k)$ for all the support points x_k . This then in turn allows us to reapply (12) with $k = 1$ and compute α_1 and β_1 . Going back to (3) with $k = 1$, we compute $\pi_2(x_k)$, whereupon (12) with $k = 2$ yields α_2, β_2 , etc. In this manner we continue until $\alpha_{n-1}, \beta_{n-1}$ have been computed. Here $n \leq N$.

x_1	w_1
x_2	w_2
$\vdots$	$\vdots$
x_N	w_N

Fig. 2. The array xw of support points and weights.

The second algorithm is based on the existence of an orthogonal similarity transformation

$$Q^T \begin{bmatrix} 1 & \sqrt{w_1} & \sqrt{w_2} & \cdots & \sqrt{w_N} \\ \sqrt{w_1} & x_1 & 0 & \cdots & 0 \\ \sqrt{w_2} & 0 & x_2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \sqrt{w_N} & 0 & 0 & \cdots & x_N \end{bmatrix} Q = \begin{bmatrix} 1 & \sqrt{\beta_0} & 0 & \cdots & 0 \\ \sqrt{\beta_0} & \alpha_0 & \sqrt{\beta_1} & \cdots & 0 \\ 0 & \sqrt{\beta_1} & \alpha_1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \alpha_{N-1} \end{bmatrix},$$

where Q is an orthogonal matrix of order $N + 1$ having the first coordinate vector $e_1 \in \mathbb{R}^{N+1}$ as its first column. *Lanczos's Algorithm* [18] carries out this transformation and thus, since the w_k and x_k are given, determines the recurrence coefficients α_k, β_k . The algorithm, unfortunately, is unstable, but can be stabilized by using ideas of Rutishauser [20]; see [16].

In Matlab, the two algorithms are implemented in the routines

$$\left. \begin{array}{l} ab = stieltjes(n, xw) \\ ab = lanczos(n, xw) \end{array} \right\} \quad n \leq N,$$

where xw is the $N \times 2$ array of the support points and weights of the given discrete measure (10); see Fig. 2.

The first routine is generally the one to be preferred, although as n approaches N , it may gradually become unstable. If such is the case, and values of n near N are indeed required, the second routine is preferable but is considerably more time-consuming than the first.

2.4. Discretization methods

The basic idea, first advanced in [7] and more fully developed in [9], is very simple: One first approximates the given measure $d\lambda$ by a discrete N -point measure,

$$d\lambda(t) \approx d\lambda_N(t), \quad (13)$$

typically by applying some appropriate quadrature scheme. Thereafter, the desired recurrence coefficients are approximated by those of the discrete measure,

$$\begin{aligned} \alpha_k(d\lambda) &\approx \alpha_k(d\lambda_N), \\ \beta_k(d\lambda) &\approx \beta_k(d\lambda_N). \end{aligned} \quad (14)$$

If necessary, the integer N is increased to improve the approximation. For each N , the approximate recurrence coefficients on the right of (14) are computed by one of the methods described in Section 2.3.

To come up with a good discretization (13) that yields fast convergence as $N \rightarrow \infty$ may require skill and inventiveness on the part of the user. But if implemented intelligently, the method is one of the most effective ones for generating orthogonal polynomials.

The seemingly complicated constructions of multicomponent discretizations to be described further on will first be motivated by a simple example.

Example 2.1. The weight function

$$w(t) = (1 - t^2)^{-1/2} + c \text{ on } [-1, 1], \quad c > 0.$$

When $c=0$, this is the Chebyshev weight, and as $c \rightarrow \infty$, one expects to recover the Legendre polynomials. Thus, in a sense, the polynomials orthogonal with respect to w “interpolate” between the Legendre and Chebyshev polynomials.

It would be very difficult to find a single quadrature scheme that would adequately approximate an integral with respect to the weight function w by a finite sum. However, by considering w as a two-component weight function, the first component consisting of the Chebyshev weight, and the second of a constant weight function, a natural discretization is obtained by applying Gauss–Chebyshev quadrature to the first component, and Gauss–Legendre quadrature to the second. Thus, the inner product with respect to the weight function w is approximated by

$$\begin{aligned} (p, q)_w &= \int_{-1}^1 p(t)q(t)(1 - t^2)^{-1/2} dt + c \int_{-1}^1 p(t)q(t) dt \\ &\approx \sum_{k=1}^M w_k^{\text{Ch}} p(x_k^{\text{Ch}})q(x_k^{\text{Ch}}) + c \sum_{k=1}^M w_k^{\text{L}} p(x_k^{\text{L}})q(x_k^{\text{L}}), \end{aligned} \quad (15)$$

where $x_k^{\text{Ch}}, w_k^{\text{Ch}}$ are the nodes and weights of the M -point Gauss–Chebyshev quadrature formula, and $x_k^{\text{L}}, w_k^{\text{L}}$ those of the M -point Gauss–Legendre quadrature formula. This in effect approximates the measure $d\lambda(t) = w(t) dt$ by a discrete N -point measure $d\lambda_N$, where $N = 2M$. Since M -point Gauss quadrature integrates polynomials of degree $2M - 1$ exactly and all inner products in the Darboux formulae (12) involve polynomials of degree at most $2n - 1$, the choice $M = n$ will insure that $\alpha_k(d\lambda) = \alpha_k(d\lambda_N)$ for all $k \leq n - 1$, and similarly for the β_k . Thus, Stieltjes’s procedure, and therefore also Lanczos’s algorithm, produces exact results. There is no need to increase N any further.

In general, the support interval $[a, b]$ of $d\lambda$ is decomposed into m subintervals

$$[a, b] = \bigcup_{\mu=1}^m [a_\mu, b_\mu], \quad m \geq 1,$$

which may or may not be disjoint. The integral of a polynomial f against the measure $d\lambda(t) = w(t) dt$ is then represented somehow in the form

$$\int_a^b f(t)w(t) dt = \sum_{\mu=1}^m \int_{a_\mu}^{b_\mu} f_\mu(t)w_\mu(t) dt, \quad (16)$$

where in the most general case f_μ will differ from f (and in fact may no longer be a polynomial) and w_μ is a positive weight function which, too, may be different from w . The *Multicomponent Discretization Method*

uses (16) with $f(t) = p(t)q(t)$ to approximate the inner product $(p, q)_w$ by applying an appropriate M -point quadrature rule to each constituent integral on the right of (16). This yields an approximation $d\lambda \approx d\lambda_N$ with $N = mM$. If the given measure $d\lambda$, in addition to the absolutely continuous component, contains also a discrete p -point component, then the latter is simply added to the (mM) -point approximation to yield an N -point approximation $d\lambda_N$ with $N = mM + p$. Using either Stieltjes's procedure or Lanczos's algorithm, we then compute the approximations $\alpha_k(d\lambda_N), \beta_k(d\lambda_N)$ of $\alpha_k(d\lambda), \beta_k(d\lambda)$ for $k=0, 1, \dots, n-1$. The integer M (and with it N) may be successively increased in an attempt to obtain sufficient accuracy.

In Matlab, the multicomponent discretization method is implemented in the routine

`[ab, Mcap, kount] = mcdis(n, eps0, quad, Mmax).`

Here, n is the number of recurrence coefficients to be computed, and eps0 the desired relative accuracy in the β -coefficients. (The α -coefficients, if they are small, or even zero, may be obtained only to an absolute accuracy of eps0 .) The input parameter `quad` is a quadrature routine that generates the M nodes and weights of the quadrature approximation of the μ th component of $d\lambda$ for the current discretization parameter M . It may be a user-defined routine tailored to the specific problem at hand, or a general-purpose routine provided automatically. The last input parameter `Mmax` is an upper bound for the discretization parameter M , which, when exceeded, causes the routine to issue an error message. The output parameter `ab` is the $n \times 2$ array of the desired recurrence coefficients, `Mcap` the value of M that yields the requested accuracy, and `kount` the number of iterations required to achieve this accuracy. The details of the discretization must be specified prior to calling the procedure. They are embodied in the following global parameters:

<code>mc</code>	the number of component intervals
<code>mp</code>	the number of points in the discrete part of the measure (<code>mp</code> = 0 if there is none)
<code>iq</code>	to be set equal to 1 if a user-defined quadrature routine is to be used, and different from 1 otherwise
<code>idelta</code>	a parameter whose default value is 1, but which is preferably set equal to 2 if <code>iq</code> = 1 and the user provides Gauss-type quadrature routines
<code>irout</code>	to be set equal to 1 if Stieltjes's procedure is to be used, and different from 1 otherwise
<code>DM</code>	if <code>mp</code> > 0 an <code>mp</code> × 2 array $[[x_1 \ y_1]; [x_2 \ y_2]; \dots; [x_{mp} \ y_{mp}]]$ containing the abscissae and jumps of the discrete component of the measure
<code>AB</code>	an <code>mc</code> × 2 array specifying the component intervals $[[a_1 \ b_1]; [a_2 \ b_2]; \dots; [a_{mc} \ b_{mc}]]$

Example 2.2. Normalized Jacobi weight function plus a discrete measure,

$$d\lambda(t) = [\beta_0^J]^{-1} (1-t)^\alpha (1+t)^\beta dt + \sum_{j=1}^p y_j \delta(t - t_j) dt, \quad \alpha > -1, \beta > -1, y_j > 0,$$

where $\beta_0^J = \int_{-1}^1 (1-t)^\alpha (1+t)^\beta dt$.

Similarly, as in Example 2.1, we use the M -point Gauss–Jacobi quadrature rule with $M = n$ and Jacobi parameters α, β to discretize the absolutely continuous component, but now add on the discrete p -point measure. As in Example 2.1, this will produce the first n recurrence coefficients exactly. The Matlab

The routine in the box below applies n -point Gauss quadrature of e^{-t} relative to the weight function $w(t) = t^a K_0(t)$ and determines the smallest n for which the relative error is less than eps0 .

```
>> global a
>> a=-1/2; N=20; Mmax=200; eps0=1e4*eps;
>> exact=sqrt(pi)*(gamma(a+1))^2/(2^(a+1)*gamma(a+3/2));
>> ab=r_modbess(N,a,Mmax,eps0); s=0; n=0;
>> while abs(s-exact)>abs(exact)*eps0
    n=n+1;
    xw=gauss(n,ab);
    s=sum(xw(:,2).*exp(-xw(:,1)));
end
>> n, s, abs(s-exact)/abs(exact)
```

For the choices made of a , N , $M_{\max}$, and $\text{eps0} = 2.22 \times 10^{-12}$, the routine yields $n = 12$, $s = 3.937402486427721$, with a relative error of 7.32×10^{-13} .

2.5. Modification algorithms

The problem to be considered here is the following: Given the recurrence coefficients of $d\lambda$, generate those of the modified measure

$$d\lambda_{\text{mod}}(t) = r(t) d\lambda(t), \quad r \text{ rational } \geq 0 \text{ on } \text{supp}(d\lambda).$$

The problem can be reduced to the one in which r is either a real linear, or a real quadratic factor or divisor, since any general real r can be written as a product of such factors and divisors. For these special cases, the problem has been solved in [8]. (Other approaches have been taken in [17,4]; see also [12, Section 3].) We briefly discuss the case of a linear factor, already solved by Galant [6].

Example 2.4. Modification by a liner factor,

$$r(t) = s(t - c), \quad c \in \mathbb{R} \setminus \text{supp}(d\lambda),$$

where $s = \pm 1$ is chosen such that r is nonnegative on the support of $d\lambda$.

The solution given by Galant is most elegantly described in linear algebra terms. It consists in applying one step of the (symmetric) shifted LR algorithm to the Jacobi matrix of the measure $d\lambda$. Specifically, the matrix $s[J_{n+1}(d\lambda) - cI]$, which by assumption is positive definite, is first Cholesky decomposed,

$$s[J_{n+1}(d\lambda) - cI] = LL^T,$$

whereupon the factors on the right are interchanged and the shift cI added back. Discarding the last row and column of the resulting matrix yields the desired Jacobi matrix of order n ,

$$J_n(d\lambda_{\text{mod}}) = (L^T L + cI)_{[1:n, 1:n]}.$$

The solution can also be described in terms of a nonlinear recurrence algorithm, which in Matlab is implemented by the routine

$$ab = \text{chri1}(N, ab0, c),$$

where $ab0$ contains the first $N + 1$ recurrence coefficients of $d\lambda$ and c is the shift parameter.

Our package includes seven additional routines `chri2.m`, `chri3.m`, ..., `chri8.m` corresponding to quadratic factors of various types, linear divisors, and quadratic divisors of different kinds. The routine `chri7.m`, for example, deals with a quadratic factor of the form $r(t) = (t - x)^2$ with $x \in \mathbb{R}$. It would be tempting to apply the routine `chri1.m` for the linear factor $t - x$ twice in succession, but this may be risky if x is inside the support of $d\lambda$. There is, however, an algorithm similar to Galant's algorithm, which applies one step of the shifted QR algorithm to the Jacobi matrix $J_{n+2}(d\lambda)$ and discards the last two rows and columns of the result to obtain $J_n(r d\lambda)$ (cf. [12, Section 3.3]).

Example 2.5. Induced orthogonal polynomials [14].

Given an orthogonal polynomial $\pi_m(\cdot; d\lambda)$ of fixed degree m , the *induced orthogonal polynomial* of degree k is orthogonal with respect to the weight function $w(t) = \pi_m^2(t) d\lambda(t)$.

Here,

$$r(t) = \prod_{\mu=1}^m (t - x_\mu)^2,$$

where x_μ are the zeros of π_m . This calls for m successive applications of the routine `chri7.m` with $x = x_\mu$, $\mu = 1, 2, \dots, m$. The routine `indop.m` shown in the box below implements this.

```
function ab=indop(N,m,ab0)
N0=size(ab0,1);
if N0<N+m, error('input array ab0 too short'), end
ab=ab0;
if m==0, return, end
zw=gauss(m,ab0);
for imu=1:m
    mi=N+m-imu;
    for n=1:mi+1
        ab1(n,1)=ab(n,1);
        ab1(n,2)=ab(n,2);
    end
    x=zw(imu,1);
    ab=chri7(mi,ab1,x);
end
```

Demo#5: Induced Legendre polynomials.

The routine shown in the next box generates the first 20 recurrence coefficients of selected induced orthogonal polynomials when $d\lambda$ is the Legendre measure.

```
>> N=20; M=11;
>> ab0=r_jacobi(N+M);
>> for m=[0 2 6 11]
    ab=indop(N,m,ab0)
end
```

Table 2

 β -coefficients of induced Legendre polynomials

k	$\beta_{k,0}$	$\beta_{k,2}$	$\beta_{k,6}$	$\beta_{k,11}$
0	2.0000000000	0.1777777778	0.0007380787	0.0000007329
1	0.3333333333	0.5238095238	0.5030303030	0.5009523810
6	0.2517482517	0.1650550769	0.2947959861	0.2509913424
12	0.2504347826	0.2467060415	0.2521022519	0.1111727541
19	0.2501732502	0.2214990335	0.2274818789	0.2509466619

By symmetry, all the α -coefficients are zero. Selected values of the β -coefficients returned by the routine (rounded to 10 decimal places) are shown in Table 2.

The procedure is remarkably stable, not only for the Legendre measure, but also for other classical measures, and for n and m as large as 320; see [11, Tables X and XI].

3. Sobolev orthogonal polynomials

These are polynomials orthogonal with respect to an inner product that involves derivatives in addition to function values, each derivative having associated with it its own (positive) measure. Thus,

$$(p, q)_S = \int_{\mathbb{R}} p(t)q(t) d\lambda_0(t) + \int_{\mathbb{R}} p'(t)q'(t) d\lambda_1(t) + \cdots + \int_{\mathbb{R}} p^{(s)}(t)q^{(s)}(t) d\lambda_s(t). \quad (18)$$

The Sobolev polynomials $\{\pi_k(\cdot; S)\}$ are monic polynomials of degree k orthogonal with respect to the inner product of (18),

$$(\pi_k, \pi_\ell)_S \begin{cases} = 0, & k \neq \ell, \\ > 0, & k = \ell. \end{cases} \quad (19)$$

These polynomials no longer satisfy a three-term recurrence relation, but like any other system of monic polynomials whose degrees increase by 1 from one polynomial to the next, they must satisfy a recurrence relation of the extended form

$$\pi_{k+1}(t) = t\pi_k(t) - \sum_{j=0}^k \beta_j^k \pi_{k-j}(t), \quad k = 0, 1, 2, \dots \quad (20)$$

In place of the Jacobi matrix, we now have an upper Hessenberg matrix of recurrence coefficients,

$$H_n = \begin{bmatrix} \beta_0^0 & \beta_1^1 & \beta_2^2 & \cdots & \beta_{n-2}^{n-2} & \beta_{n-1}^{n-1} \\ 1 & \beta_0^1 & \beta_1^2 & \cdots & \beta_{n-3}^{n-2} & \beta_{n-2}^{n-1} \\ 0 & 1 & \beta_0^2 & \cdots & \beta_{n-4}^{n-2} & \beta_{n-3}^{n-1} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & \beta_0^{n-2} & \beta_1^{n-1} \\ 0 & 0 & 0 & \cdots & 1 & \beta_0^{n-1} \end{bmatrix}. \quad (21)$$

In the case $s = 0$ corresponding to ordinary orthogonal polynomials, one has $\beta_j^k = 0$ for $j > 1$, and the matrix H_n is tridiagonal. It can be symmetrized by a (real) diagonal similarity transformation and then becomes the Jacobi matrix $J_n(d\lambda_0)$ (cf. (4)). When $s > 0$, symmetrization is no longer possible, since some of the eigenvalues of H_n may well be complex.

3.1. Moment-based algorithms

We define modified moments similarly as in (7), but now a separate set of them for each measure $d\lambda_\sigma$,

$$m_k^{(\sigma)} = \int_{\mathbb{R}} p_k(t) d\lambda_\sigma(t), \quad k = 0, 1, 2, \dots, \sigma = 0, 1, \dots, s. \quad (22)$$

For simplicity, we use the same set of polynomials $\{p_k\}$ for each measure and assume, as in (8), that they satisfy a three-term recurrence relation. In analogy to (9), there is now a unique map that takes the first $2n$ modified moments of all the measures $d\lambda_\sigma$ into the recurrence coefficients β_j^k ,

$$[m_k^{(\sigma)}]_{k=0}^{2n-1}, \sigma = 0, 1, \dots, s \mapsto [\beta_j^k], k = 0, 1, \dots, n-1, j = 0, 1, \dots, k. \quad (23)$$

The conditioning of this map has been studied in [28], and an algorithm, analogous to the modified Chebyshev algorithm, developed (for $s = 1$) in [15]. The corresponding routine in Matlab is

$$[B, \text{normsq}] = \text{chebyshev_sob}(N, \text{mom}, \text{abm}).$$

Here, N is the n in (23), mom the $2 \times 2N$ array of the first $2N$ modified moments corresponding to $d\lambda_0$ and $d\lambda_1$, and abm the $(2N - 1) \times 2$ array of the recurrence coefficients in (8). The output variable B is the $N \times N$ matrix of the recurrence coefficients β_j^k , $k = 0, 1, \dots, N - 1$, $0 \leq j \leq k$, where β_j^k occupies the position $B(j + 1, k + 1)$ of the matrix B ; all remaining elements of B are zero. The routine also returns the optional N -vector normsq of the squared norms $\|\pi_k\|_S^2$ of the Sobolev orthogonal polynomials. If abm is absent in the list of input parameters, then ordinary moments are assumed ($a_k = b_k = 0$).

Example 3.1. The polynomials of Althammer [1].

These are the Sobolev orthogonal polynomials with $s = 1$ and $d\lambda_0(t) = dt$, $d\lambda_1(t) = \gamma dt$ on $[-1, 1]$, where $\gamma > 0$. There is a fairly obvious choice of the polynomials $\{p_k\}$ for defining the modified moments, namely the monic Legendre polynomials. All modified moments in this case, by orthogonality, are zero except for

$$m_0^{(0)} = 2, \quad m_0^{(1)} = 2\gamma.$$

In Matlab, the recurrence matrix B for the Althammer polynomials is generated as shown in the box below (where $N = n$ and $g = \gamma$).

```
>> N=20; g=1;
>> %g=0;
>> mom=zeros(2,2*N);
>> mom(1,1)=2; mom(2,1)=2*g;
>> abm=r_jacobi(2*N-1);
>> B=chebyshev_sob(N,mom,abm);
```

Fig. 3. Legendre vs. Althammer polynomial.

Demo#6: Legendre vs. Althammer polynomials.

The routine in the box below generates and plots the Sobolev polynomial of degree $N=20$ corresponding to $s = 1$ and $\gamma = 0$ (Legendre polynomial) resp. $\gamma = 1$ (Althammer polynomial). It is assumed that the matrix B has already been generated by the routine for Althammer polynomials shown above with $N = 20$ and $g = 0$ resp. $g = 1$.

```
>> N=20;
>> pi=zeros(N+1,1); np=500; y=zeros(np+1,1);
>> for it=0:np
    t=-1+2*it/np;
    pi(1)=1;
    for k=1:N
        temp=0;
        for l=1:k
            temp=temp+B(l,k)*pi(k-l+1);
        end
        pi(k+1)=t*pi(k)-temp;
    end
    y(it+1)=pi(N+1);
end
>> x=linspace(-1,1,np+1);
>> hold on
>> plot(x',y)
>> plot([-1 1],[0 0], '--')
>> hold off
```

The plot for the Legendre polynomial is shown in Fig. 3 in the left frame, and the one for the Althammer polynomial in the right frame.

Interestingly, for the Legendre polynomial the envelope of the extreme points is convex on top and concave at the bottom, whereas for the Althammer polynomial it is the other way around. Note also that $\pi_{20}(\pm 1) = 0.7607 \times 10^{-5}$ for the Legendre, and $\pi_{20}(\pm 1) = 0$ for the Althammer polynomial.

3.2. Discretization algorithm

The analogue for Sobolev orthogonal polynomials of the Darboux formulae (12) is

$$\beta_j^k = \frac{(t\pi_k, \pi_{k-j})_S}{(\pi_{k-j}, \pi_{k-j})_S}, \quad j = 0, 1, \dots, k, \quad (24)$$

with the inner product $(\cdot, \cdot)_S$ defined as in (18). The *Discretized Stieltjes Algorithm*, similarly as for ordinary orthogonal polynomials, consists in combining the formulae (24) with the recurrence relation (20), discretizing the inner products in (24) by suitable quadrature schemes. We chose to approximate the absolutely continuous component of each measure $d\lambda_\sigma$ by a Gauss-type quadrature rule,

$$(p, q)_{d\lambda_\sigma} \approx \sum_{k=1}^{n_\sigma} w_k^{(\sigma)} p(x_k^{(\sigma)}) q(x_k^{(\sigma)}), \quad \sigma = 0, 1, \dots, s, \quad (25)$$

and to add on any discrete component of $d\lambda_\sigma$ if present. In Matlab, the quadrature schemes are identified by an $md \times 2(s+1)$ array xw ,

$$xw = \begin{matrix} x_1^{(0)} & \cdots & x_1^{(s)} & w_1^{(0)} & \cdots & w_1^{(s)} \\ x_2^{(0)} & \cdots & x_2^{(s)} & w_2^{(0)} & \cdots & w_2^{(s)} \\ \vdots & & \vdots & \vdots & & \vdots \\ x_{md}^{(0)} & \cdots & x_{md}^{(s)} & w_{md}^{(0)} & \cdots & w_{md}^{(s)} \end{matrix}$$

where $md = \max(n_\sigma)$. In each column of xw the entries after $x_{n_\sigma}^{(\sigma)}$ resp. $w_{n_\sigma}^{(\sigma)}$ (if any) are ignored by the routine. The routine itself has the form

$$B = \text{stieltjes_sob}(N, s, nd, xw, a0, \text{same}),$$

where $nd = [n_0, n_1, \dots, n_s]$, $a0 = \alpha_0(d\lambda_0)$, and same is a logical variable to be set equal to 1 if all quadrature rules have the same nodes, and equal to 0 otherwise. If $\text{same} = 1$, the routine takes advantage of significant simplifications that are possible and reduce running time.

Example 3.2. The Althammer polynomials, revisited.

The box below shows the generation of the recurrence matrix B for the Althammer polynomials using the routine `stieltjes_sob.m`.

```
>> N=20; g=1;
>> nd=[N N]; s=1; a0=0; same=1;
>> ab=r_jacobi(N);
>> zw=gauss(N,ab);
>> xw=[zw(:,1) zw(:,1) zw(:,2) g*zw(:,2)];
>> B=stieltjes_sob(N,s,nd,xw,a0,same);
```

The results are identical with those produced by the routine `chebyshev_sob.m`. There is no restriction, however, on the parameter s when using the routine `stieltjes_sob.m`.

3.3. Zeros

If $\pi(t)$ is the vector of the first n Sobolev orthogonal polynomials,

$$\pi^T(t) = [\pi_0(t), \pi_1(t), \dots, \pi_{n-1}(t)],$$

then the recurrence relation (20) can be written in matrix form as follows,

$$t\pi^T(t) = \pi^T(t)H_n + \pi_n(t)e_n^T,$$

where e_n is the last coordinate vector in $\mathbb{R}^n$. If $t = \tau_v$ is a zero of π_n , the last term vanishes, implying that τ_v is an eigenvalue of the matrix H_n and $\pi^T(\tau_v)$ a corresponding (left) eigenvector. Thus, the zeros of Sobolev orthogonal polynomials can be computed as eigenvalues of an upper Hessenberg matrix. In Matlab, this is done by the routine `sobzeros.m` shown in the box below.

```
function z=sobzeros(n,N,B)
H=zeros(n);
for i=1:n
    for j=1:n
        if i==1
            H(i,j)=B(j,j);
        elseif j==i-1
            H(i,j)=1;
        elseif j>=i
            H(i,j)=B(j-i+1,j);
        end
    end
end
z=sort(eig(H));
```

Here B is the recurrence matrix of order N for the Sobolev orthogonal polynomials, and $n \leq N$. The zeros are arranged in increasing order.

Demo#7: The zeros of the Althammer polynomial of degree 20 with $\gamma = 1$.

Assuming that the matrix B has already been generated by either the modified Chebyshev algorithm or the Stieltjes procedure as described in Sections 3.1 and 3.2, the box below shows the Matlab commands

and output (only the positive zeros are shown, rounded to 12 decimals).

```
<< N=20; z=sobzeros(N,N,B)
z =
    8.05392515636e-02
    2.39532838077e-01
    3.92325438959e-01
    5.34960935873e-01
    6.63745343244e-01
    7.75342384688e-01
    8.66859942239e-01
    9.35924777578e-01
    9.80740571465e-01
    1.00000000000e-01
```

Judging from how well the symmetry of the roots is satisfied, the results appear to be accurate to all digits shown except the last, which may be in error by one or two units. Generating the matrix B by the modified Chebyshev algorithm or Stieltjes's procedure produces the same results to this accuracy, but the Stieltjes procedure is considerably slower (by a factor of about 14) than the modified Chebyshev algorithm.
